Topics:

Production of Particles
Transport / Confinement
Observed Nonthermal Radiation
Interpretation
Future Gamma-Ray Perspectives

Clusters & SBs

H.J. Voelk, Kashiwa 2002

Starburst Galaxies:

External Galaxies should also produce CRs from sources similar to the Galaxy - plus possibly through other mechanisms, like overall accretion or an AGN.

Starburst galaxies assumed to be analogous to Milky Way. However, significantly enhanced star formation rate (SFR). Assumed to result in higher CR production rate. Different form and strength of Galactic Wind.

Comparison with Galaxy important for:

1. Contribution of recent SF to CR production, compared to other processes (e.g. Central Black Hole, SN Ia [old stars], X-ray binaries from old component)
 2. CR propagation process (convection vs. diffusion)
- Universal CR origin ? (Universal CR intensity ?)

Clusters & SBs

H.J. Voelk, Kashiwa 2002

Possible examples: M82 (North), NGC 253 (South)

Closest SB galaxies at distances of ~ 3.2 Mpc (M82), and ~ 2.5 Mpc (NGC 253).

NGC 253:

R.A. = 0h 47min 45.3sec

Declination = - 25 degrees 17' 18", for NGC 253

Projected optical size = $27.5' \times 6.8'$ \rightarrow extended γ -ray source for $< 6'$ resolution? Starburst nucleus smaller.

SN rate: 0.1/yr to 0.3/yr; u_{CR} (NGC 253) \cong 10 to 100 u_{CR} (Galaxy). Galactic Wind in thermal X-rays. High FIR flux.

(IC model: Goldshmidt & Rephaeli [1995, using LS wind model])

Analogous: IC 342, with R.A. 03h 42'; Dec. \sim 67 deg 56'; Incl'n \sim 25 deg? (Böker et al. 1997)

75 - 90 MPH

Fig. 3—The new spectral image in Fig. 1. The contours are per cent of total intensity from NOC 219 at 6.13 GHz, with a resolution of 0.7". The reference field is 0.12" beam. The peak surface brightness is 4.12 Jy beam⁻¹. Contour levels are: -12, 12, 24, 36, 48, 60, 72, 84, 96, 108, 120, 132, 144, 156, 168, 180, 192, 204, 216, 228, 240, 252, 264, 276, 288, 300, 312, 324, 336, 348, 360, 372, 384, 396, 408, 420, 432, 444, 456, 468, 480, 492, 504, 516, 528, 540, 552, 564, 576, 588, 600, 612, 624, 636, 648, 660, 672, 684, 696, 708, 720, 732, 744, 756, 768, 780, 792, 804, 816, 828, 840, 852, 864, 876, 888, 900, 912, 924, 936, 948, 960, 972, 984, 996, 1000. The level for this contour is 29 mJy beam⁻¹. An asterisk (*) denotes the reference star in the field.

CHANDRA pictures in hard X-rays

NGC 253

M82

Clusters & SBs

H.J. Voelk, Kashiwa 2002

M82:

High **radio synchrotron intensities** in central region ($r = 300$ pc; $h = 100$ pc). Minimum energy in CRs plus magnetic field \rightarrow CR energy density $u_{CR} \cong 80$ eV/cm³ and $B^2/4\pi = u_B \cong 50$ μ G. (Assumption $e/p = 1/100$)

100 times larger than in Galaxy ($\cong 1$ eV)

FIR radiation field (100 μ m) equally strong: $u_{rad} \cong 200$ eV/cm³ $\cong u_B$

Soft X-rays indicate fast wind $v =$ few 1000 km/s

Mean (molecular) gas density in SB nucleus $\cong 140$ H-atoms/cm³

Supernova rate $\leq 1/(3$ yr) $\leq 10 \times$ Galactic SN rate \rightarrow **Convective escape, consistent with SNRs as sources for energetic particles:**

$\rightarrow dE(CR)/dt = \alpha v(SN)$, α universal? (Völk et al. (1989))

Recently: Strong Chandra X-ray sources ! Slower wind ?

Clusters & SBs

H.J. Voelk, Kashiwa 2002

M82 in gamma rays ?

SB nucleus \equiv 40 arcsec (γ -ray point source)

Small **hadronic** γ -ray flux expected due to large distance (marginal for Northern instruments ?) :

$$F_{\gamma} (> 100 \text{ MeV}) = 1.3 \times 10^{-9} \text{ ph/cm}^2 \text{ sec};$$

$$F_{\gamma} (> E) = 2.6 \times 10^{-13} (E / 1 \text{ TeV})^{-1.1} \text{ ph/cm}^2 \text{ sec}$$

Hard particle energy spectrum, at least towards cutoff, due to strongly convective transport (no escape softening) !

→ IC flux perhaps higher: Even though both gas density (in SB nucleus) and target photon field \sim factor 100 larger than in Galaxy, larger IC emission volume in halo !

YET: Not detected by HEGRA CT-System in 35 hrs ! (< 0.02 Crab)

NGC 253 (Chandra)

Correlation of soft X-rays with $H\alpha$ up to 10 kpc above disk: thermal wind ! $dM/dt \sim 24$ Solar masses (Strickland et al. 2002)

Heavily absorbed source of hard X-rays in nuclear SB region (~ 300 pc radius; thickness ~ 150 pc). $L(X) > L(\text{Edd})[1.4 M(\text{Sun})]$ Intermediate mass BH ? Gamma-ray source? $B \sim 0.3$ mG (Weaver et al. 2002)

NGC 253 in gamma rays ?

EGRET: Only upper limits (also M82)
OSSE (< 10 MeV): detected
TeV: Hadronic due to high B-field ?
But large halo volume!

Clusters of Galaxies

- Largest gravitationally bound objects in the Universe. Mass dominated by the diffuse Intracluster gas by factor 3 to 5 compared to the galaxies (typically several 100 galaxies per cluster)
- Contain a representative sample of thermal matter in Universe ("Confinement")
Typical gas temperatures = several keV.

Production of Particles; Transport / Confinement

Probably also confinement of nonthermal particles over a Hubble time ("Cosmological CRs") → Entropy history of cluster formation.

From chemical abundances of IC gas (about $0.4 \times$ Solar) huge amount of Star Formation/galaxy in clusters: must have happened in these constituent galaxies. Strong CR production in core collapse SNRs? Removal and reacceleration in Galactic Winds to IC medium?

Clusters & SBs

Production of Particles, cont'd

Main particle energization is gravitational. Factor > 10

Extreme case: More or less mere adiabatic gravitational contraction after acceleration as a result of the SBs in galaxies (little additional entropy production). Unlikely, even though accretion shocks not strong!

Alternative: (Primary) particle acceleration also - or even dominantly - in (relatively weak) accretion shocks of subclusters onto the main cluster during ongoing cluster formation ?

Additionally: FR II-jet acceleration ?

Observed Nonthermal Radiation

Observed low energy Synchrotron/IC emission testifies to recent acceleration: Radio "Halos", EUV excess, Nonthermal X-rays.

No high energy gamma-rays yet detected !

B-fields possibly large \sim microG, from galactic Winds ?

(Brecher & Burbidge 1972)

- 1) Radio synchrotron compatible with IC emission in radio and X - rays **for $B \sim 0.1$ microG**

Steady injection over last 3×10^9 yr.

Break between EUV and X-rays due to radiative losses

Observed Nonthermal Radiation, cont'd

2) Difficulty for high **B-field ~ 1 microG**:

No IC X-ray emission from radio electrons possible
(X-rays thermal (superhot component, Bremsstrahlung?)
(Sarazin & Lieu 1998; Atoyan & Völk 2000):

IC EUV possible from electron distribution with
 $\gamma(\text{EUV}) < \gamma(\text{max}) < \gamma(\text{radio})$

Due to "Old" electrons = cosmological electrons.

Sharp cutoff for $E < 100 \text{ MeV}$.

Adiabatic compression during cluster contraction

Radio electrons separate component, continuously injected
or due to secondaries.

Clusters & SBs

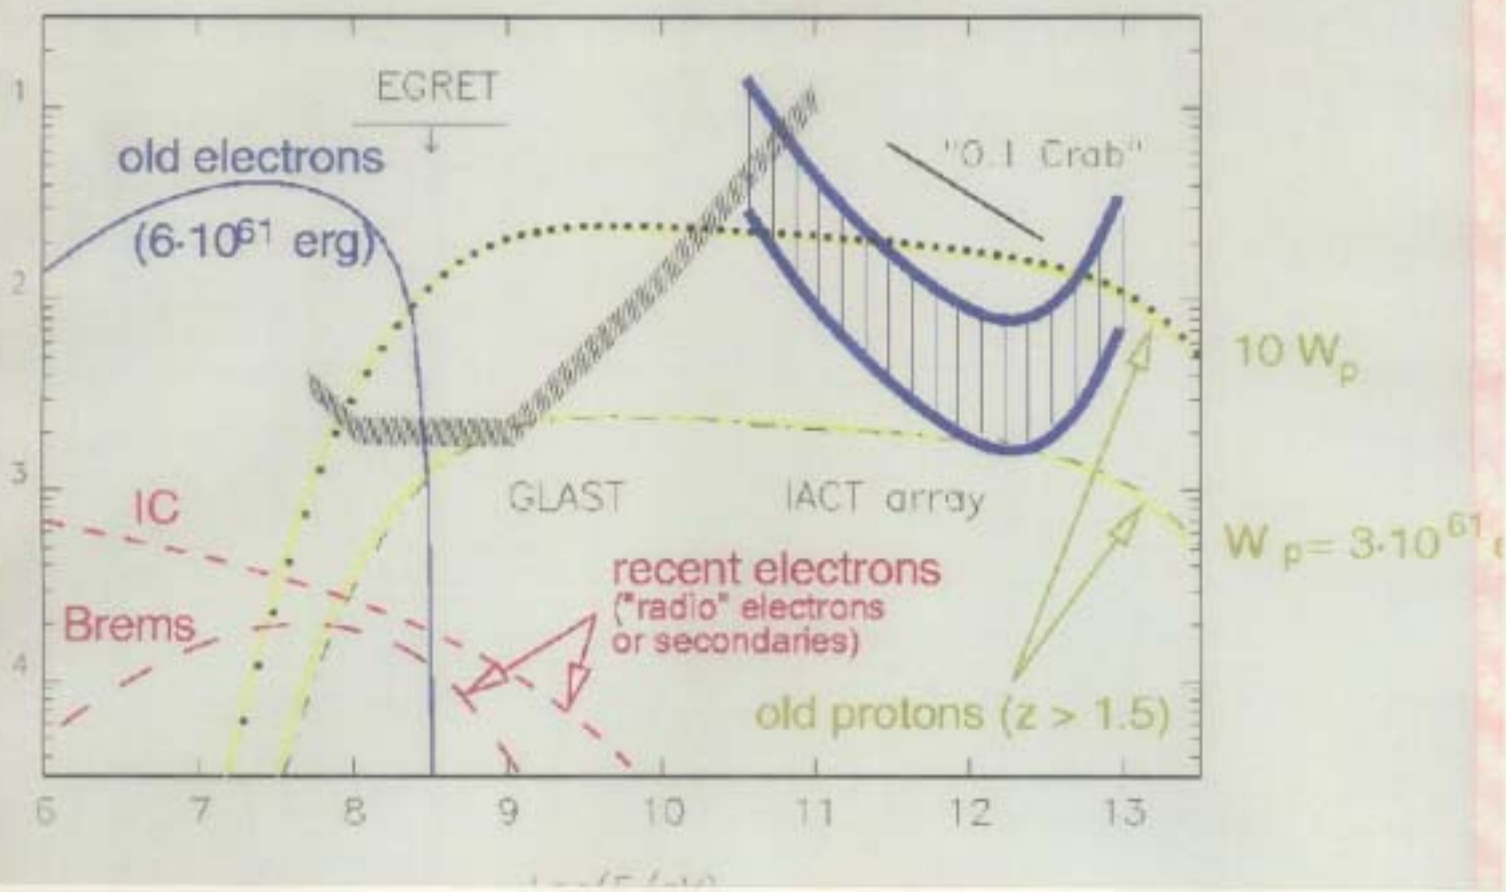

H.J. Voelk, Kashiwa 2002

Old electrons produce Bremsstrahlung up to 300 MeV.

Hadrons should contain large energy with hard spectrum
(=source spectrum)

$W(\text{Protons}) \sim 1/30 W(\text{Gas}) \sim 3 \times 10^{62}$ ergs

Future Gamma-Ray Perspectives

Depend strongly on source extension (> 1 degree extended)

Might be observable with GLAST (1yr)

HESS, CANGAROO, VERITAS, MAGIC in 50 h (5 sigma)

GLAST should see the "old" EUV electrons
